The conversion of AlGaAs alloys to AlₓOᵧ has received much attention for a wide variety of applications. Rarely, however, do such applications require large-scale lateral oxidation (i.e. 100s of microns). Oxidation of AlAs to AlₓOᵧ for use as a broadband Saturable Bragg reflector (SBR) requires an AlₓOᵧ/GaAs mirror with lateral dimensions greater than 300 µm. For the SBR structure described below, the simulated bandwidth extends from 1200 nm to 1800 nm with greater than 99.5% reflectivity.

The layers within the SBR are grown using gas-source molecular beam epitaxy and are shown in Figure 26(a). The SBR structure contains an 8 period GaAs/AlAs quarter-wave stack grown on a GaAs substrate. The AlₓOᵧ layer is initially grown as AlAs that is later oxidized. The AlAs layer thickness corresponds to a quarter wavelength in AlₓOᵧ (n=1.66) plus a 10% shrinkage upon oxidation. The active region consists of an InP/InGaAs quantum well emitting near λ=1550 nm. The InP/InGaAs active region is not lattice-matched to the GaAs substrate and hence a defective interface exists between the active region and the Bragg reflector.

The AlAs is converted to AlₓOᵧ using a thermal oxidation process [apparatus shown in Figure 26(b)]. The structure was oxidized using a constant flow of N₂ bubbled through deionized water maintained at a constant temperature of 90°C. The oxidation was performed at several different furnace temperatures. From 435°C to 415°C delamination of the active region occurs due to high interfacial stress upon oxidation. Sufficient lateral oxidation depths of over 300 µm are achieved, however, when the temperature is reduced to 400°C (Figure 27). As an example of an application of the broadband SBR, the structure was utilized to initiate lasing in a Cr³⁺:YAG laser. High-reflectivity, wide stop-band, and low loss are required for the Cr³⁺:YAG laser cavity. With the oxidized SBR as an end mirror, self-starting with pulses as short as 35 fs have been achieved with Kerr lens mode-locking.
